The effect of a low-intensity magnetic field combined with polarized light on the microvascular links in periodontal tissues during orthopaedic treatment by fixed dentures in patients with partial secondary adentia and periodontal diseases were determined using an experiment on laboratory animals. The experiment was made on selected 107 random-bred rats. The animals were divided into three groups: control group 1, control group 2, and the experimental group. A dynamic analysis of morphological changes in the tissues of pathologically changed periodontium in three groups of animals demonstrated that, as compared to other animals, the rats from the experimental groups, following experimental magneto phototherapy, had early elimination of inflammation (1 hour after termination of the impact) in all gingival components and perifocal structures due to vaporization of inflammatory cells, activation of vessels (plethora and a noticeable increase in number), while regeneration and full epithelialization of the gingival pocket were completed 2 days after termination of magneto phototherapy.

Keywords: partial secondary adentia, periodontal diseases, magneto phototherapy, animal studies

THE EFFECT OF MAGNETOPHOTOTHERAPY ON MORPHOLOGICAL CHANGES OF TISSUES OF PATHOLOGICALLY CHANGED PERIODONTIUM

Представлены результаты экспериментального исследования по изучению влияния низкоинтенсивного магнитного поля в сочетании с поляризованным светом на звенья микроциркуляторного русла в тканиях периodontона на 107 рандомбрёдных крысах. Динамический анализ морфологических изменений в тканях патологически измененного периodontона в трех группах животных показал, что по сравнению с остальными животными
The efficacy of comprehensive treatment of patients with periodontal diseases depends on the use of additional treatment and prevention interventions. Application of physical factors for comprehensive treatment of inflammatory diseases is an important part of comprehensive treatment. The use of physical factors at different stages of disease makes it possible not only to eliminate the initial signs of the pathological process, but also to reduce the intensity of its clinical manifestation and the probability of relapse, thereby giving the most optimal treatment outcomes [3, 4, 9, 12].

Combined or supplementing physiotherapeutic treatment of periodontal diseases provides a number of advantages: synergized action of several factors has an obvious therapeutic effect; reducing the intensity and duration of the procedures and of the course of treatment; and mutual action of the physical factors at the biological, physical and physico-chemical stages of their effect [1, 6, 11].

Magneto phototherapy causes analgesic and hypotensive effects, as well as pronounced antiedemic and anti-inflammatory action in the tissues. The action and efficacy of magneto phototherapy are defined by physiological and curative effects of combined physical factors, i.e., light and magnetic field, on one hand, and by the interaction of these factors and the shifts induced in the body, on the other hand.

The use of magneto phototherapy at different stages of dental treatment stimulates biosynthetic processes and generation of phosphates rich in energy, enhances regional circulation and microcirculation, stimulates erythropoiesis, decreases aggregation of blood platelets, enhances oxygen capacity of blood, etc. Combined use of magnetic field and phototherapy causes magneto photoelectric effect (Kikoin-Noskov effect), inducing a powerful electromotive force in the tissues. Magnetic fields facilitate deep penetration of optical radiation into the tissue and increase the range of optical radiation perception by the cells. Magnetic fields cause the splitting of energy levels and spectral lines of atomic systems in the tissues, thereby imparting them additional energy (Zeeman effect). Combined effect of light and magnetic field enhances each of the factors and increases the total therapeutic activity of the method [5, 14].

The goal of the research was to study the character of morphological changes in the tissues of pathologically changed periodontium after exposure to magneto phototherapy in animal testing.

Material and Methods. In order to reach this goal, the experiment included 107 random-bred rats of both sexes, 209–243g of body weight, divided into 3 groups. All animals were kept in absolutely identical conditions: the use of additional treatment and prevention interventions. Application of physical factors for comprehensive treatment of inflammatory diseases is an important part of comprehensive treatment. The use of physical factors at different stages of disease makes it possible not only to eliminate the initial signs of the pathological process, but also to reduce the intensity of its clinical manifestation and the probability of relapse, thereby giving the most optimal treatment outcomes [3, 4, 9, 12].

Control group 1 (5 random-bred rats) was used to study periodontal tissues in order to define the condition of the healthy gum, followed by pathomorphological evaluation of the healthy gum biopsy material.

Control group 2 (42 random-bred rats) included laboratory animals with experimentally induced periodontitis, for which magneto phototherapy was used, followed by pathomorphological evaluation of the biopsy material.

The exponential group (60 random-bred rats) included laboratory animals with experimental periodontitis, for which magneto phototherapy was applied, followed by pathomorphological evaluation of the tissue samples taken directly after physical impacts, after 1 hour, 2 hours, 3 hours, as well as every day from day 1 to day 8 after treatment. Also, the character of pathomorphological changes in the tissues of pathologically changed periodontium after magneto phototherapy was determined.)

Physical impact was exerted on the gum area, the mandibular central incisors. The experimental area was identical in all rats studied in this group. Keratinized stratified squamous epithelium (KSSE) of the gum was identical in all rats studied in this group.

The experiment was terminated, upon completion of the period of animals observation (the experimental group and control group 2), by instant decapitation after intraperitoneal thiopental narcosis administered as 1 ml of 5 % thiopental sodium per 100 grams of the body weight, abiding by the principles of bioethics (according to GLP). The material for microscopy studies was taken immediately after magneto phototherapy, and after 1, 2 and 3 hours, as well as each day from day 1 to day8 after treatment. The obtained micro preparations were tested, and their micro photos were produced by a DMLS microscope with software (Leica, Germany).

Results and Discussion. The control group. The morphological studies demonstrated that the condition of periodontal tissues was within the norm during the experimental observation periods. The microscopic structure of the gum was identical in all rats studied in this group. Keratinized stratified squamous epithelium (KSSE) of the gingival crevice and the free part of the gum is, basically, uniformly thin, with thickened spots, mostly in the free part of the gum, and stratified. The epithelial ridges were predominantly wide and low, some of them thin and elongated, which forms the relevant microstructure (papillary layer) of the gum lamina propria (LP). The gingival crevice was narrow and short. The gum LP represented non-structured connective tissue (CT), loose in the papillary layer, and a loosely delimited net-like layer of the non-structured CT and bulky collagen fibres (CFs).

Control group 2. One day (subgroup I) after termination of the stress impact, the microscopic changes of the gum were similar in all studied rats. In the mucoperiosteal flap of the animals, changes in the gingival crevice epithelium (uneven thickness with segmental elimination of the layers, dystrophy and cytolysis of the basal cells, few elongated cells of the granular layer with single dust granules, transformation of its cells to keratinocytes and
formation of the cornified layer) were observed. Intensive purulent proliferative inflammation with destruction and separation of the junctional epithelium was found and, as a consequence, noticeable deepening of the gingival crevice and formation of the gingival pocket, periosteal microabscess, pus accumulation and purulent detritus in the deepened and expanded gingival crevice, inflammation spreading to the gum LP, the periosteum of alveolar process of the jaw bone, and the periodontal ligament.

It was observed that the LP of the free segment of the gum included small spots of proliferative inflammation, abundant slit-like lymph capillaries (optically empty), non-functioning few blood capillaries (without blood components in the lumen), with thickened walls and dystrophy of endotheliocytes. The gingival epithelium had smoothed papilla of the basal layer.

On the 2d day (subgroup II), the morphological indicators matched the same indicators of subgroup I (Fig. 1A).

On the 8th day (subgroup VIII), a deep gingival crevice with inhomogeneous gingival epithelium, mostly thin with segmental destruction of the surface layers, was observed. In its middle and end, an expressed elongation of epithelial ridges was observed, with disorientation and growth into the gum LP. In the distal part, the beginning focal regeneration of epithelium with disordered arrangement of cells, cytolysis of the epithelial cells at the crevice bottom with exposure of the gum LP (ulceration), and a focal growth of the maturing granulation tissue in this area with signs of serous inflammation were visualized. Relatively bulky spots of a similar granulation tissue inside the periodontal ligament were identified with sharply expressed hyperplasia of the cell component of the latter. In the apical segment of the free part of the gum, SSE dystrophy and surface erosion with a small spot of lymphocytes and signs of epithelialization were identified. Slight oedema of the gum LP, focal dilated and merging optically-empty thin-wall lymphatic vessels, diffusely scattered cells compressed minor and plethoric capillaries with few blood components (up to 10–15 in the field of microscope with 200X), small spots of perivascular lymphocyte penetration, and pockets of ectatic and plethoric venules in the gingival crevice bottom were visualized (Fig. 2A).

The experimental group. Microscopic structures of the gum in all tested rats were identical within each subgroup.

One hour after magneto phototherapy (subgroup II – E), SSE cornified layer was not visualized (pre-coagulation changes), glittering and uniformly thin. Singular vacuolar (vaporization) cells were found in the spinous layer, and pre-coagulation changes of SSE cells remained. Total elimination of inflammatory lymph from the gingival pocket and formation of dense fibrous tissue on the edge of the gum SSE defect in the distal part and the gingival pocket bottom was present. Disseminated vaporization of inflammatory cells of the gum LP was seen, with destroyed (coagulation and pre-coagulation changes) in a
On the 2nd day (subgroup VI – E) after termination of magneto phototherapy, a uniform thin glittering epithelial layer was visualized, with out cornified layer. SSE of the free edge of the gum had moderate thickness with clear cellular and layer differentiation; the granular layer was thick in some spots. The gingival pocket was without any content, its edge was epithelialized over its entire length, and epithelium was represented by a narrow bundle with disordered epithelial cells. The gum LP included compactly packed CFs, with no signs of inflammatory infiltration; retention of a few (1 or 2) mononuclear cells in the lumen of lymph capillaries that did not move beyond their wall was observed (Fig. 1B).

On the 8th day after magneto phototherapy (subgroup X – E), SSE of the free edge of the gum contained, as in the control group, glittering, granular, spinous and basal layers were present, without epithelial ridges. The gingival pocket was narrow without any content. The gingival pocket edge was surrounded by a relatively narrow SSE strip, in some places with a relatively broad granular layer and a narrow layer of spinous and basal cells; without a glittering layer or epithelial ridges in some spots. The fixing area was represented by a narrow strip of dense fibrous tissue and a narrow strip of longitudinal fibrous tissue.

Conclusions. Specific microscopic changes of the gum and their trends, noticeably differing from the gum microscopic structure in rats of the control group and the experimental group, were found:

Dynamic changes in the gum microscopic structure were observed 1 hour after the exposure and included total elimination of inflammatory lymph of the gingival pocket and inflammatory cells of the gum LP, or remaining pre-coagulation changes; after 2 hours they included signs of beginning regeneration of the gingival pocket (delimited by a narrow bundle of mature fibrous tissue); after 3 hours, restoration of the cell structure of the gum epithelium, partial epithelialization of the gingival pocket, which was more obvious after 1 day and almost full after 2 days. Ectasia (and plethora) of the blood and lymph sinusoidal capillaries of the gum LP with mononuclear cells retention in the latter was observed after 3 hours, with a moderate growth of intensity during the subsequent observation periods; this sign remaining up to 8 days.

Thus, early elimination of inflammation (1 hour after termination of the impact) in all gum components and perifocal structures due to vaporization of inflammatory cells, activation of vessels (plethora and a noticeable increase in number) was found after the exposure to magneto phototherapy, while regeneration and complete epithelialization of the gingival pocket completed 2 days after termination of magneto phototherapy.

In the of study was investigated the antinociceptive action of derivatives of quinazolinone-4 in 187 male and 196 female rats, including females rats in the different stages of the estrous cycle: diestrus ½ and proestrus /estrus in models of nociceptive responses induced by chemical stimuli (formalin test, «acetic cramps»), to assess the level of organization of the peripheral pain sensation. Substances (laboratory code numbers: PGFA – I, II, III, IV, V, VI, VII) at a dose of 2/10 of the molecular weight in mg/kg, reference drugs: metamizole sodium and lidocaine was administered once intraperitoneally 40 minutes before administration of chemical irritants. Control and males received respectively solubilizate Tween-80 and saline (0.4 ml intraperitoneally) under similar conditions. The 4-quinazolinone derivatives compounds I–IV, VI, VII were investigated as potential analgesics. Substance I–IV, VI and VII exhibited analgesic activity in male and female rats. Substances I, VI, VII have analgesic effects on female rats in phase of the estrous cycle diestrus ½; substance I–IV, VI – in the stage of prooestrus/estrus. Among the investigated derivatives of quinazolinone-4 compound VI is a leader in analgesic activity.
